

Climatological Station Networks for Potential Evaporation Estimates
in the British Isles. B.G.Wales-Smith

Introduction and Source of Data

Estimates of Potential Evaporation (PE) over river catchments are required for water balance calculations.

In this simple preliminary investigation monthly fields of P.E. (March-October 1970) for the two areas shown in Figure 1. are examined. The first is a generally lowland area bordered, to the east, by the North Sea; the second area is topographically complex in every sense.

The PE estimates used are taken from the P.E. tables published as part of the Soil Moisture Deficit Bulletin. The stations used are those considered to have adequate data of quality good enough to produce useful PE estimates.

Analysis of P.E. Estimates

The PE estimates, given in Tables 1 and 2 were plotted on monthly maps (Figs 2 and 3). Simple analyses were constructed by the addition of isopleths at 5 mm intervals on the basis that the PE values between stations were linearly distributed.

A transparent overlay (Fig.4), carrying a grid of 25 points at 20 Km intervals in the x and y directions, was applied to each monthly map and PE values (to the nearest millimetre) were read off and tabulated (Tables 3 and 4).

In the first case, the centre point (13) was placed over Honington and in the second case over Abbotsinch.

At the foot of each column in Tables 3 and 4 is shown (i) the average of 25 grid point values (ii) the %age error involved in using the Point 13 (Honington or Abbotsinch) computed value as an estimate of the average value over square A B C D ($10,000 \text{ Km}^2$), (iii) the average of the 9 grid points 7-9, 12-14, and 17-19 values and (iv) the %age error involved in using the computed Point 13 value as an estimate of the average value over square E F G H ($3,600 \text{ Km}^2$).

Percentage errors are small for both squares in both areas. Using the smaller square (i.e. one calculation to represent $60 \times 60 \text{ Km}$) all percentage errors are $\leq 6\%$.

Conclusions

Assuming that the PE estimates are of good quality (i.e. produced from good class, area-representative data) and that the simple analyses are fair approximations to those which would have been obtained from considerably denser station networks, it appears that one station per $60 \times 60 \text{ Km}$ square can provide a

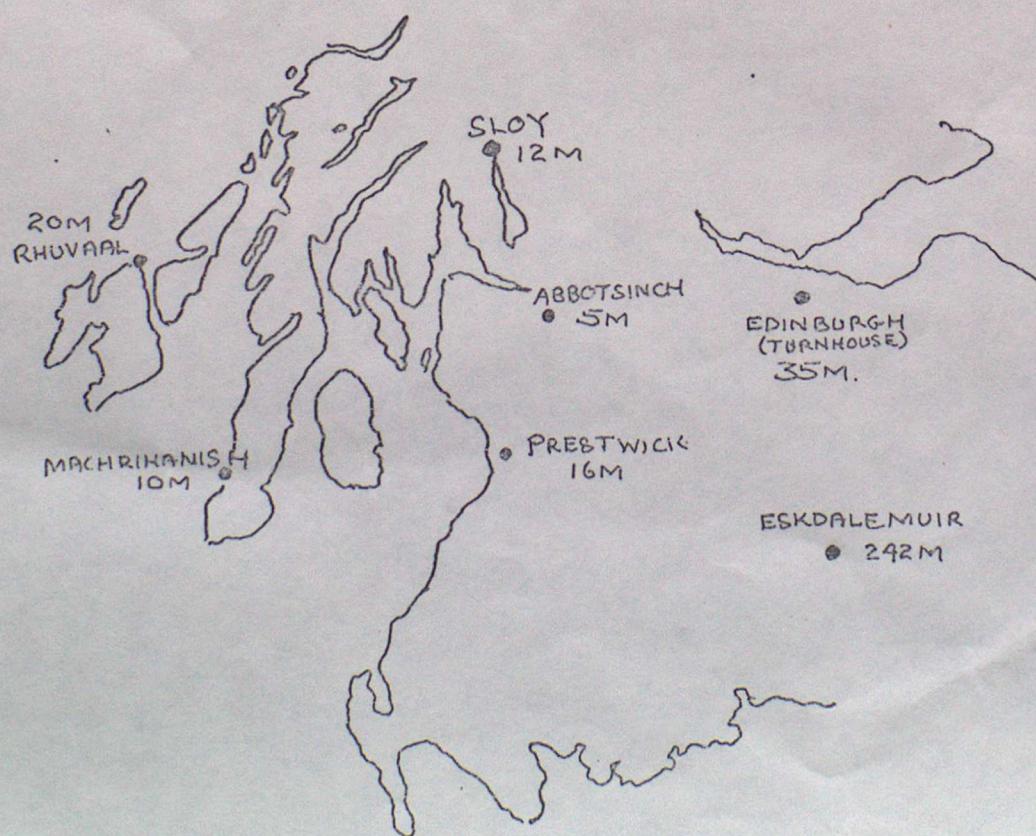

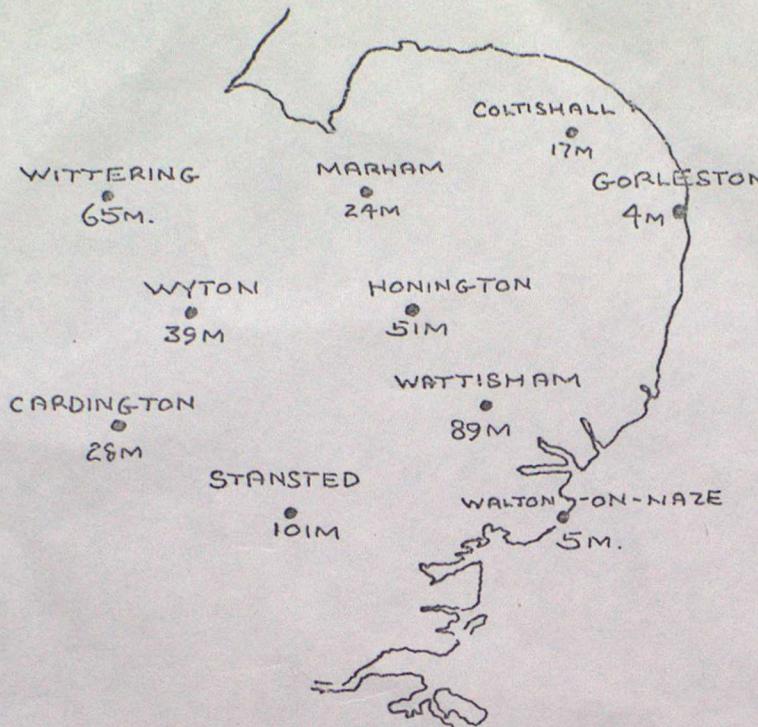

general, monthly PE estimate "accurate" to within about 6% for the months March to October.

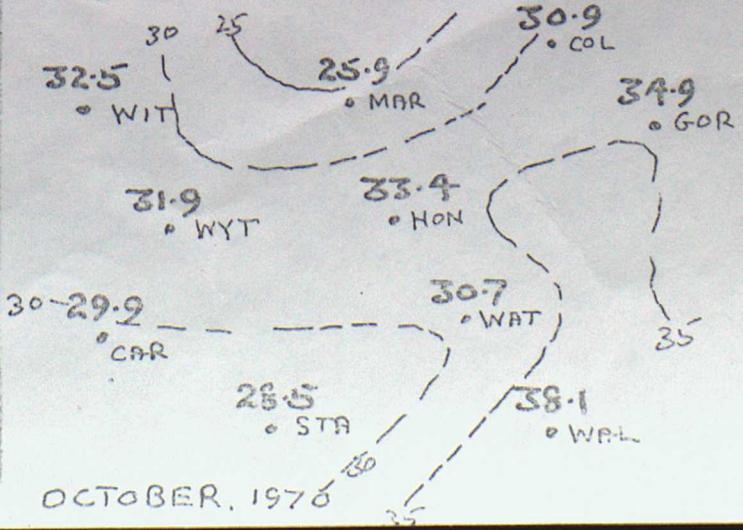

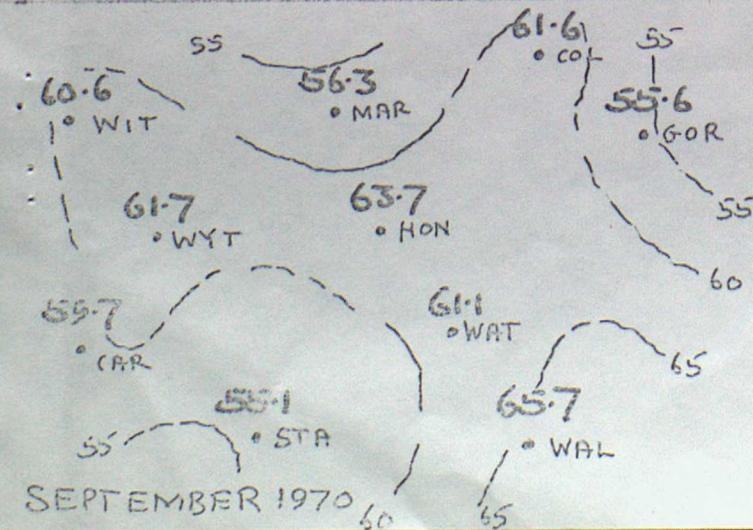

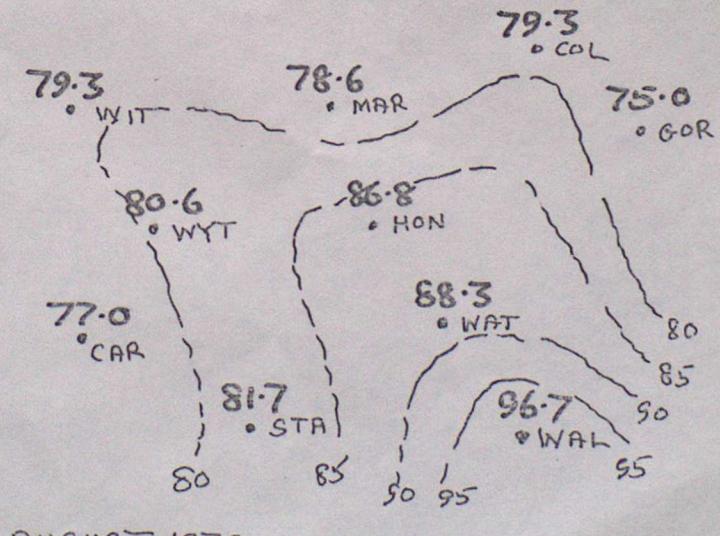

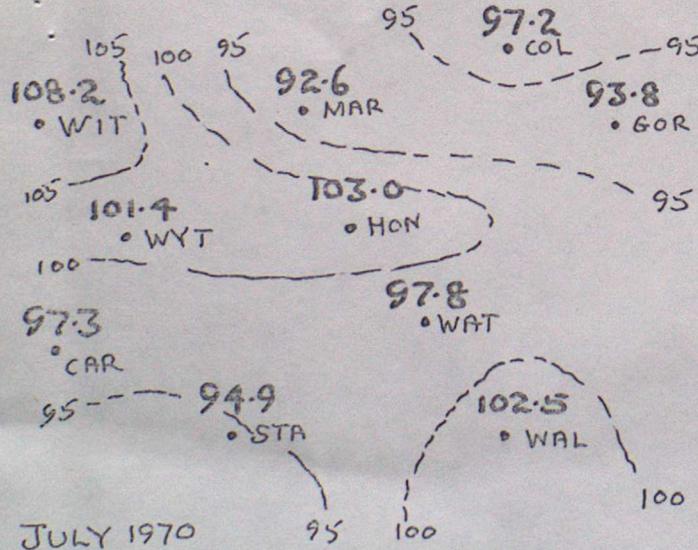

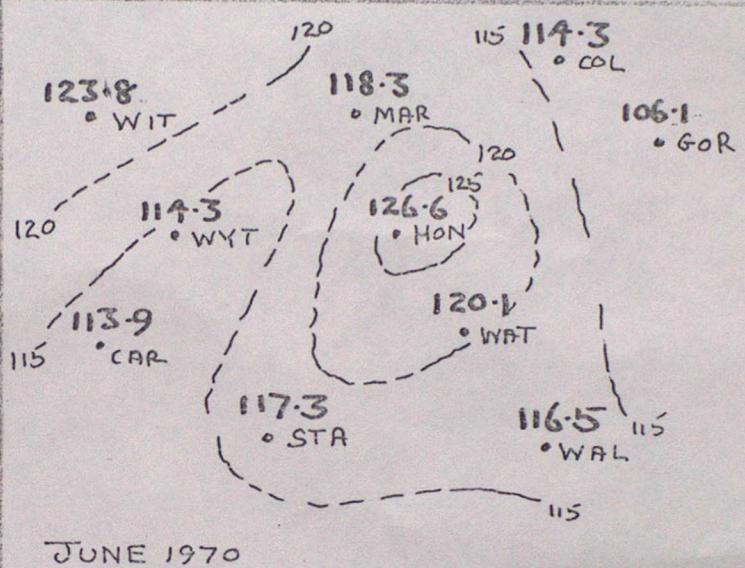

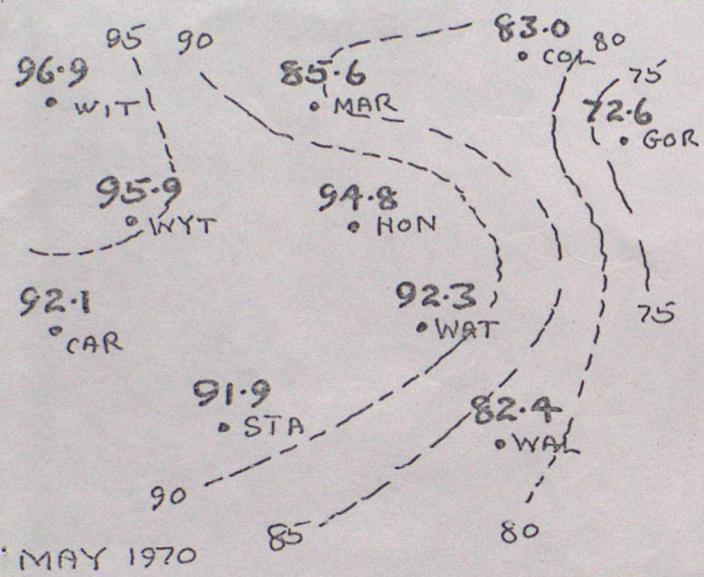

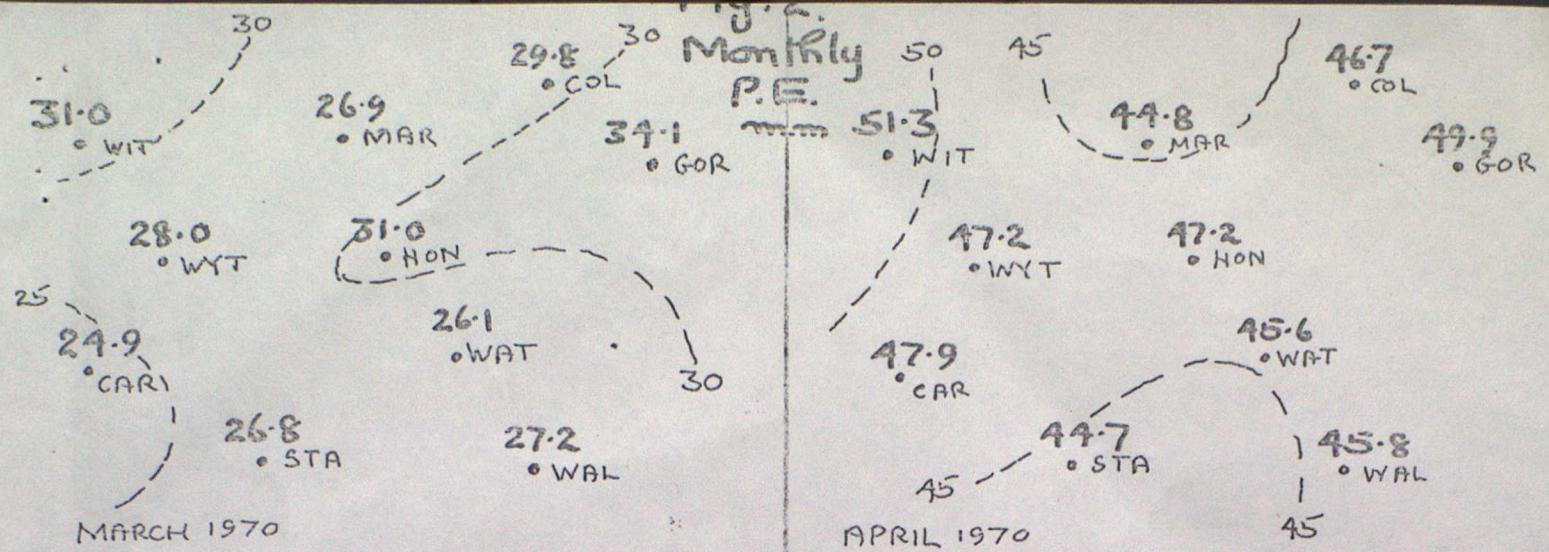

Recent work in the hydrometeorological branch of the Meteorological Office has shown that, in the months with appreciable average values of PE, the sums of 6 5-day and 3 10-day estimates are very close to the value of the corresponding 30-day estimate. Since, in addition the sum of 2 5-day estimates is usually very close to the value of the corresponding 10-day estimate it is probably fair to suggest that the network relationship found in this investigation could be applied to 10 and 5-day estimates as well as to monthly estimates.
